TITLE: On the Thermal History of the Earth ✓

PERIODICAL: Izvestiya Akademii nauk SSSR, Seriya geofizicheskaya,
1960, Nr 2, pp 243-252 (USSR)

ABSTRACT: Thermal calculations of the originally cold Earth are given. Models of the Earth were considered which had different radioactive elements, specific heat of the core and thermal radiation. The formation of the crust is assumed to have been a lengthy process lasting 3×10^9 years. The calculated effect of the thermal radiation, together with the thermal flow was found to agree with observational data in the case of smaller content of the radioactive elements. A comparison of the theoretical results for both the continental and oceanic regions of the crust showed that the difference between their thermal flows is smaller than that relating to the thickness of the crust. This difference is caused by the flow being affected not only by the crust itself but also by deeper layers. This fact explains why the thermal flows of oceans differ from those of continents. The results of investigations are ✓

TITLE:

Some Calculations of the Thermal History of the Moon

PERIODICAL:

Doklady Akademii nauk SSSR, 1960, Vol. 133, No. 1,
pp. 44-47

TEXT: By the calculations under review the authors try to explain the development of the Moon with the accumulation of cold bodies. The heat balance of the Moon is assumed to be determined by its radioactive elements. In accordance with V. S. Safronov, the Moon is assumed to have originated $0.23 \cdot 10^9$ years ago, and at its surface, temperature is assumed to be 0°C at all times. In the selection of the content of radioactive elements the authors base on analyses of meteorites made by A. P. Vinogradov and others. The heat conductivity is assumed to be $\lambda = 1.2 \cdot 10^{-2}$ cal/cm.sec.grad. Calculations made under these assumptions and discussed here were carried out with the hydrointegrator devised by V. S. Luk'yanov at the

Tsentral'nyy nauchno-issledovatel'skiy institut stroitel'stva Mintransstroy
(Central Scientific Research Institute for Construction of the Mintransstroy).
Calculations of the initial heating of the Moon are treated first. For a
density of 3.3 g/cm^3 the authors obtain a temperature in the center of
the Moon, which is 190°C higher than the surface temperature. The beginning
of the melting process in the center is approximately obtained at the
time $t = 0.5 \cdot 10^9$ (with an age of $0.23 \cdot 10^9$ years being assumed for the
Moon) for a variant of the content of radioactive elements and $t = 0.7 \cdot 10^9$
for another variant. In a detailed discussion of the processes which
arose in the melting of the Moon it is shown that a thin solid shell,
which is denser than the underlying melt, could not exist. Moreover,
the transition from the heating and melting of the Moon to its cooling
and solidification was accompanied by a reduction of radioactive elements.
This reduction was caused by the natural decay and by the surface losses
of the Moon. In a calculation of the cooling process of the Moon it is
shown that about 3 - 3.5 billion years after the Moon began to cool, the
original temperature distribution made itself manifest. Moreover, the
temperature depends on the distribution of radioactive elements and on

heat conductivity. The model of the Moon for which the cooling was calculated is shown. This model features an iron core ($r = 685$ km) and a shell. The content of radioactive elements is taken from analyses of iron meteorites according to A. G. Starkova (Ref. 2). The authors conclude from the results obtained that the shell has today a thickness of 500 - 700 km, that the layer underneath is not completely molten, and that the iron core has melted to at most 15%. It is finally stated that the temperature distribution today is primarily dependent on the content of radioactive elements, and that the shell is at least 500 - 700 km thick. TITLE: Determination of microquantities of copper in silicon tetrachloride

SOURCE: Zavodskaya laboratoriya, v. 31, no. 12, 1965, 1447

TOPIC TAGS: microchemical analysis, silicon, copper, luminescent material

ABSTRACT: The spectral analysis and luminescence methods for determining microquantities of copper in silicon tetrachloride are compared. Authors recapitulate previously published data on the two methods and conclude that while both methods permit the determination of $1 \cdot 10^{-8}$ microquantities of copper in a 50 g batch, the error in the luminescence method is 10 times less than in the spectral method (see table). Best results were obtained by the luminescence determinations in the concentration range 5×10^{-6} to 5×10^{-8} copper. Orig. art. has: 1 table.

I. P. McEvily et al.

cesses in the brain were arrested by the adrenalin; or it may have been impeded so that it lagged behind the glycolytic processes, as was indicated by the fact that the performed lactic acid content increased in the rabbit brain tissue. After the intravenous injection of glucose (at a hyperglycemia of 300 mg. %) the process of autoglycolysis rose in the rabbit brains, which suggested an increase in consumption of reserves. The rate of lactic acid increase also rose in the direction of autoglycolysis, upon the addition of substrate; this pointed to an enhanced activity of the enzymes of the processes of anaerobic catabolism. At the same time, the glu-
